Abstract—This paper presents a metric-based matching algorithm to estimate the robot planar displacement by matching dense two-dimensional range scans. The contribution is a geometric distance that takes into account the translation and orientation of the sensor at the same time. This result is used in the two steps of the matching - estimation process. The correspondences between scans are established with this measure and the minimization of the error is also carried out in terms of this distance. As a result, the translation and rotation are compensated in this framework simultaneously. In fact, this is the contribution with respect to previous work that addressed only translation or translation and rotation but separately. The new technique has been implemented and tested on a real vehicle. The experiments illustrate how it is more robust and accurate than prior techniques, especially facing large rotation errors. At the end of the paper, we give an extension of our distance measure to 3D range-data matching problems.

I. INTRODUCTION

One of the key issues in autonomous mobile robots is to keep track its position. Usually this problem is addressed by using the on board sensors to gather information of the environment for localization and mapping purposes. Many applications in robotics use techniques to estimate the robot displacement among successive range measurements. This paper presents a new method that achieves this goal. In robotics these techniques have been successfully applied to a wide range of issues as an ameliorated odometry. For example to improve the performance of simultaneous localization and mapping algorithms [22], [9], [11], to build local maps for indoor and outdoor navigation [15], [12], [16] and to implement people tracking systems for mobile platforms [21]. Furthermore, the pattern recognition and machine vision communities have also addressed the sensor matching problem in the context of 3D data registration, object recognition or scene understanding [20], [13]. In this paper, we also give the perspective to apply our technique to these communities.

The objective of the scan matching techniques is to compute the relative motion of a vehicle between two consecutive configurations by maximizing the overlap between the range measurements obtained at each configuration. They usually assume an initial estimation of the relative pose of the scans that is provided by the vehicle odometry.

One of the main differences between the existing algorithms is the usage or not of high-level entities such as lines or planes. In structured environments, one can assume

the existence of polygonal structure in the environment [8], [6], [4]. These methods are fast and work quite well for indoor environments. However, they limit the scope of application to the extraction of geometric features that are not always available in unstructured environments. On the other hand, a great deal of work has been done to perform in any type of scenario dealing with raw data. Roughly, these techniques are based on an iterative process that estimates the sensor displacement that better explains the overlap between the scan measurements. For example [3] constructs a piecewise continuous differentiable density that models on a grid the probability to measure a point, and then, apply the Newton's algorithm. By converting the scans to statistical representations, [23] iteratively compute the crosscorrelation that results in the displacement. In [7] the motion parameters are estimated using a constrained velocity equation for the scanned points.

However, the most popular methods usually follow the Iterative Closest Point (ICP) algorithm (principle borrowed from the computer vision community [2]). They are based on an iterative process where they first compute the correspondences between the scans, and then they minimize the distance error to compute the sensor displacement [14], [19], [10], [1], [18]. This process is repeated with this new estimate until convergence. A common feature of most versions of ICP is the usage of the Euclidean distance to establish the correspondences and to apply the least squares. However, this distance does not account for the fact that points far from the sensor could be far from its correspondent due to rotations of the sensor. To overcome this limitation [14] proposed to compute two set of correspondents, one by the Euclidean distance and other by the angular distance (to capture the sensor rotation). The gain in accuracy is however lost in complexity and convergence since the method builds two sets of matchings and performs two minimizations (rotation and translation) at each iteration. We understand that this is a central problem of the ICP algorithms: to find a way to measure (to find the *closest* correspondent and to apply the minimization) in such a way that it captures the sensor translation and rotation at the same time.

Our contribution resides in the definition of a new distance measure in the image space of the sensor that takes into account both, translation and rotation at the same time. The distance between two points is the norm (in a

Fig. 1. This Figure depicts the scan-matching problem: to compute the sensor relative displacement between poses using the range information. Due to the discrete nature of the data it is assumed local structure in the reference scan (a segment that joins successive points).

sense we are going to define) of the smallest rigid body transformation that leads a point to the other one. I.e our distance naturally depends on translation and rotation. We use this distance in both steps of the ICP algorithm:

- 1) matching of each point of a scan with the closest feature of the other scan in terms of our distance,
- 2) computation of relative displacement by least square minimization of the errors (in terms of our distance).

With this formulation we obtain results that ameliorate by far the algorithm that we were using [14] (the most used algorithm for scan matching) in terms of robustness and precision. Furthermore, we present in the paper the extension to the 3D problem, which could be used by the robotics, computer vision and graphics communities that use the ICP algorithm to address sensor motion estimation, location and map building, object recognition, pattern analysis, image registration, and scene understanding among others.

The paper is distributed as follows: in Section II we describe the ICP algorithm. In Section III-C we show how to use our distance to match points of two laser scans and we express the least square criterion we minimize, based on this distance measure. In Section IV, we discuss the experimental results and we compare our method with existing methods. Finally we draw our conclusions in Section V and we discuss possible extensions and future work in Section VI.

II. THE ITERATIVE CLOSEST POINT (ICP) ALGORITHM

Given a reference scan S_{ref} , the new scan S_{new} and a rough estimation q_0 of the relative displacement of the sensor between the scans, the objective is to estimate the real displacement $q = (x, y, \theta)$ between them (Figure 1).

The ICP algorithm addresses this problem with an iterative process in two steps. At each iteration k , there is a search of correspondences between the points of both scans. Then the estimation of relative displacement q_k is improved through a minimization process. The process is repeated until convergence:

- 1) First let place each point p'_i of S_{new} in the system of reference S_{ref} using the estimation q_k , $p''_i = q_k(p'_i)$. Then, due to the discrete nature of the data, it is assumed a local structure in S_{ref} between successive points (p_i, p_{i+1}) of S_{ref} [14] (Figure 1). Thus, the correspondent point to p''_j is the closest point p_j belonging to one of the segments $[p_i, p_{i+1}]$:

$$\min\{d(p''_j, [p_i, p_{i+1}])\} \quad (1)$$

The result is a set C of n correspondences (p_j, p''_j) .

- 2) Compute the displacement estimation q_{min} that minimizes the mean square error between pairs of C . The criterion to minimize is q :

$$E_{dist}(q) = \sum_{i=1}^n d(q(p_j), p''_j)^2 \quad (2)$$

If there is convergence the estimation is q_{min} , otherwise we iterate again with $q_{k+1} = q_{min}$.

The ICP uses the Euclidean distance in both steps of the algorithm. The contribution of this work is a distance that takes into account translation and rotation simultaneously. In order to use this new concept in the ICP we need to define the distance, give the expression of distance point to segment, and formulate the least squares in terms of the new distance. In the next section we address these issues.

III. DISTANCE MEASURE AND TOOLS ASSOCIATED

In this section, we introduce first our distance measure in the plane, defined as the minimum norm among the rigid body transformations that move a point to another one.

A. Distance point to point

A rigid body transformation in the plane is defined by a vector $q = (x, y, \theta)$ representing the position and orientation ($-\pi < \theta < \pi$) of the scanner sensor in the plane. We define the norm of q as :

$$\|q\| = \sqrt{x^2 + y^2 + L^2\theta^2} \quad (3)$$

where L is a positive real number homogeneous to a length. Given two points $p_1 = (p_{1x}, p_{1y})$ and $p_2 = (p_{2x}, p_{2y})$ in \mathbb{R}^2 , we define a distance between p_1 and p_2 as follows:

$$d_p(p_1, p_2) = \min\{\|q\| \text{ such that } q(p_1) = p_2\} \quad (4)$$

where

$$q(p_1) = \begin{pmatrix} x + \cos \theta p_{1x} - \sin \theta p_{1y} \\ y + \sin \theta p_{1x} + \cos \theta p_{1y} \end{pmatrix} \quad (5)$$

It can be easily checked that d_p is a real distance satisfying for any p_1 and p_2 :

- 1) $d_p(p_1, p_2) = d_p(p_2, p_1)$
- 2) $d_p(p_1, p_2) = 0$ implies $p_1 = p_2$
- 3) $d_p(p_1, p_3) \leq d_p(p_1, p_2) + d_p(p_2, p_3)$

Unfortunately, there is no closed form expression of the above distance w.r.t. the coordinates of the points. However, we can compute an approximation valid when the minimum norm transformation is small, by linearizing (5) about $\theta = 0$. The set of rigid-body-transformations satisfying

$q(p_1) = p_2$ can be approximated by the set of solutions (x, y, θ) of the following system:

$$\begin{aligned} x + p_{1x} - \theta p_{1y} &= p_{2x} \\ y + \theta p_{1x} + p_{1y} &= p_{2y} \end{aligned}$$

The set of solutions is infinite and can be expressed by:

$$\begin{aligned} x &= p_{2x} - p_{1x} + \theta p_{1y} \\ y &= p_{2y} - p_{1y} - \theta p_{1x} \end{aligned}$$

where θ is a parameter for the set of solutions. Let us recall that according to (4), we need to find the solution that minimizes the norm of $q = (x, y, \theta)$. For a given θ , this norm is given by the following equation, after substituting the above expressions of x and y into (3):

$$\|q\| = (\delta_x + \theta p_{1y})^2 + (\delta_y - \theta p_{1x})^2 + L^2 \theta^2$$

where $\delta_x = p_{2x} - p_{1x}$ and $\delta_y = p_{2y} - p_{1y}$. Expanding the above expression, we obtain a polynomial of degree 2 in θ :

$$\|q\|^2 = a\theta^2 + b\theta + c$$

with $a = p_{1y}^2 + p_{1x}^2 + L^2$, $b = 2(\delta_x p_{1y} - \delta_y p_{1x})$ and $c = \delta_x^2 + \delta_y^2$. Notice that $a > 0$ implies that this expression has a unique minimum for $\theta = -b/(2a)$ and the value of this minimum is given by

$$\begin{aligned} \|q\|^2 &= \frac{-b^2 + 4ac}{4a} \\ &= \frac{-(\delta_x p_{1y} - \delta_y p_{1x})^2 + (p_{1y}^2 + p_{1x}^2 + L^2)(\delta_x^2 + \delta_y^2)}{p_{1y}^2 + p_{1x}^2 + L^2} \\ &= \delta_x^2 + \delta_y^2 - \frac{(\delta_x p_{1y} - \delta_y p_{1x})^2}{p_{1y}^2 + p_{1x}^2 + L^2} \end{aligned}$$

Finally, the distance between p_1 and p_2 is approximated by:

$$d_p^{ap}(p_1, p_2) = \sqrt{\delta_x^2 + \delta_y^2 - \frac{(\delta_x p_{1y} - \delta_y p_{1x})^2}{p_{1y}^2 + p_{1x}^2 + L^2}} \quad (6)$$

Notice that as expected, our distance is smaller than the Euclidean distance, since this latter is the norm of the translation between p_1 and p_2 and therefore is bigger than the minimum norm.

To better understand the properties of this distance measure, let us compute the iso-distance curves. Again, we do not have the exact expression of the iso-distance curves but if we use approximation (6), we can prove that the iso-distance curves relative to d_p^{ap} :

$$\{p_2 \in \mathbf{R}^2 \text{ such that } d_p^{ap}(p_1, p_2) = c\}$$

are ellipses centered on p_1 with principal axes (p_{1x}, p_{1y}) and $(-p_{1y}, p_{1x})$ and lengths $c\sqrt{1 + \frac{\|p_1\|^2}{L^2}}$ and c (see Figure 2).

Fig. 2. The iso-distance curves of d_p^{ap} are ellipses centered on p_1 .

B. Distance point to segment

In this subsection we give an expression of the distance point to segment (1). Let us consider a point p_1 and a line segment defined by two points s_1 and s_2 . The distance between p_1 and segment $[s_1 s_2]$ is defined by:

$$d_{ps}(p_1, [s_1 s_2]) = \min_{\lambda \in [0,1]} d_p(p_1, (1-\lambda)s_1 + \lambda s_2) \quad (7)$$

Let us denote by $d(\lambda) = d_p(p_1, (1-\lambda)s_1 + \lambda s_2)$ the distance between p_1 and the point on segment $[s_1 s_2]$ of parameter λ . Following the same reasoning as in previous Section, we can approximate this distance by:

$$d(\lambda)^2 \approx \delta_x(\lambda)^2 + \delta_y(\lambda)^2 - \frac{(\delta_x(\lambda)p_{1y} - \delta_y(\lambda)p_{1x})^2}{p_{1y}^2 + p_{1x}^2 + L^2} \quad (8)$$

where

$$\delta(\lambda) = (\delta_x(\lambda), \delta_y(\lambda)) = s_1 - p_1 + \lambda(s_2 - s_1) \quad (9)$$

Substituting (9) into (8), we get a polynomial of degree 2 in λ :

$$d(\lambda)^2 \approx a\lambda^2 + b\lambda + c$$

with the following coefficients:

$$\begin{aligned} a &= u_{2x}^2 + u_{2y}^2 - \frac{(p_{1y}u_{2x} - p_{1x}u_{2y})^2}{p_{1x}^2 + p_{1y}^2 + L^2} \\ b &= 2(u_{2x}\delta_{1x} + u_{2y}\delta_{1y}) - 2\frac{(p_{1y}u_{2x} - p_{1x}u_{2y})(\delta_{1x}p_{1y} - \delta_{1y}p_{1x})}{p_{1x}^2 + p_{1y}^2 + L^2} \\ c &= \delta_{1x}^2 + \delta_{1y}^2 - \frac{(\delta_{1x}p_{1y} - \delta_{1y}p_{1x})^2}{p_{1x}^2 + p_{1y}^2 + L^2} \end{aligned}$$

where $u_2 = (u_{2x}, u_{2y}) = s_2 - s_1$ and $\delta_1 = (\delta_{1x}, \delta_{1y}) = s_1 - p_1$. Coefficient a is positive and therefore the above expression has a unique minimum in λ , for $\lambda = \frac{-b}{2a}$:

$\frac{-b^2+4ac}{4a}$. The expression of the approximation of the distance $d_{ps}(p_1, [s_1 \ s_2])$ for small rotations is thus given by:

$$d_{ps}(p_1, [s_1 \ s_2]) \approx \begin{cases} d_p(p_1, s_1) & \text{if } \lambda < 0 \\ d_p(p_1, s_2) & \text{if } \lambda > 1 \\ \sqrt{\frac{-b^2+4ac}{4a}} & \text{if } 0 \leq \lambda \leq 1 \end{cases}$$

and the closest point to p_1 on $[s_1 \ s_2]$ in these three cases is respectively s_1 , s_2 and $s_1 - \frac{b}{2a}s_2$.

C. Least Square Minimization

To compute and minimize the criterion proposed in (2), we use the following notation: the coordinates of p_i and p_i'' are respectively (p_{ix}, p_{iy}) and (p_{ix}'', p_{iy}'') . We assume that θ is small and thus we linearize the above expression about $\theta = 0$. We get the following expression:

$$E_{dist}(q) = \sum_{i=1}^n \delta_{ix}^2 + \delta_{iy}^2 - \frac{(\delta_{ix}p_{iy} - \delta_{iy}p_{ix})^2}{p_{iy}^2 + p_{ix}^2 + L^2} \quad (10)$$

where

$$\begin{aligned} \delta_{ix} &= p_{ix}'' - p_{ix} + p_{iy}\theta - x \\ \delta_{iy} &= p_{iy}'' - p_{iy} - p_{ix}\theta - y \end{aligned}$$

(10) is quadratic w.r.t. q :

$$E_{dist}(q) = q^T A q - 2b^T q + c$$

where c is a constant number, A is a symmetric matrix

$$A = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{12} & a_{22} & a_{23} \\ a_{13} & a_{23} & a_{33} \end{pmatrix}$$

$$\begin{aligned} a_{11} &= \sum_{i=1}^n \frac{p_{ix}^2 + L^2}{p_{ix}^2 + p_{iy}^2 + L^2} & a_{12} &= \sum_{i=1}^n p_{ix}p_{iy} \\ a_{13} &= \sum_{i=1}^n p_{iy}(p_{ix}^2 + p_{iy}^2 - 1) & a_{22} &= \sum_{i=1}^n \frac{p_{iy}^2 + L^2}{p_{ix}^2 + p_{iy}^2 + L^2} \\ a_{23} &= \sum_{i=1}^n p_{ix}(1 - p_{ix}^2 - p_{iy}^2) & a_{33} &= \sum_{i=1}^n \frac{L^2(p_{ix}^2 + p_{iy}^2)}{p_{ix}^2 + p_{iy}^2 + L^2} \end{aligned}$$

and

$$b = \begin{pmatrix} \sum_{i=1}^n \frac{(p_{ix}^2 + L^2)(p_{ix}' - p_{ix}) + p_{ix}p_{iy}(p_{iy}' - p_{iy})}{p_{ix}^2 + p_{iy}^2 + L^2} \\ \sum_{i=1}^n \frac{(p_{iy}^2 + L^2)(p_{iy}' - p_{iy}) + p_{ix}p_{iy}(p_{ix}' - p_{ix})}{p_{ix}^2 + p_{iy}^2 + L^2} \\ -L^2 \sum_{i=1}^n \frac{p_{iy}(p_{ix}' - p_{ix}) - p_{ix}(p_{iy}' - p_{iy})}{p_{ix}^2 + p_{iy}^2 + L^2} \end{pmatrix}$$

The value of q that minimizes $E_{dist}(q)$ is thus

$$q_{min} = A^{-1}b$$

IV. EXPERIMENTAL RESULTS

In this Section we outline the experimental results. We implemented the method on a wheelchair mobile robot equipped with a Sick LMS-200 laser range scanner.

In order to compare our method (metric-based ICP, MbICP in short) with existing scan matching techniques, we used the widely known IDC algorithm [14]. We did not implement this method *ad hoc* for the comparison, since we have this tool working in our laboratory [17], [15], [16]. As proposed by the authors, our IDC algorithm uses two types of correspondences and interpolates in

Fig. 3. This Figure the two scans used in the experiment.

both between successive range points (local structure). We also reject outliers using visibility criteria [14] and range criterions [18]. Furthermore we use a trimmed version of the ICP to manage the correspondences [5] that improves the least squares minimization, and a smooth criterion of convergence [18]. We also implemented these features in the MbICP algorithm. In order to show a fair comparison, we used the same values for common parameters (actually we used our IDC previous parameters for the MbICP), and we only tuned the metric length in the MbICP (the only *ad hoc* parameter). In the experiments, we found that $L = 2$ gave the best results.

We outline next two types of experiments. The first evaluates the properties of the MbICP algorithm by matching a pair of scans (Figure 3). The second one is a run with the vehicle to evaluate the global algorithm performance (Figures 5 and 6).

The first experiment consisted on matching two different scans for different location errors. They were both acquired in the same sensor location but at different times. Thus, the scans are different due to the sensor noise and we know precisely the ground truth $(0, 0, 0)$. We remark that we selected a place to take the scans where the range information was more or less equally distributed in all directions (Figure 3), which is a well-conditioned situation for both methods. To test both algorithms, we added random noise to the initial location estimate up to 0.2m in x and y , and up to 45° in θ . Notice how large are the maximum errors especially in rotation¹. We repeated the experiment 1000 times starting at random locations. Convergence of the algorithm was achieved when the error ratio was below 0.0001% and the maximum number of iterations was 500.

Figure 4a depicts the final estimates of both the MbICP and IDC, and Figure 4b the number of iterations of both algorithms. The MbICP converged all the times and all the estimates concentrate around the true solution $(0, 0, 0)$. In

¹Previous comparisons of scan matching [18] use maximum rotation errors up to 6° .

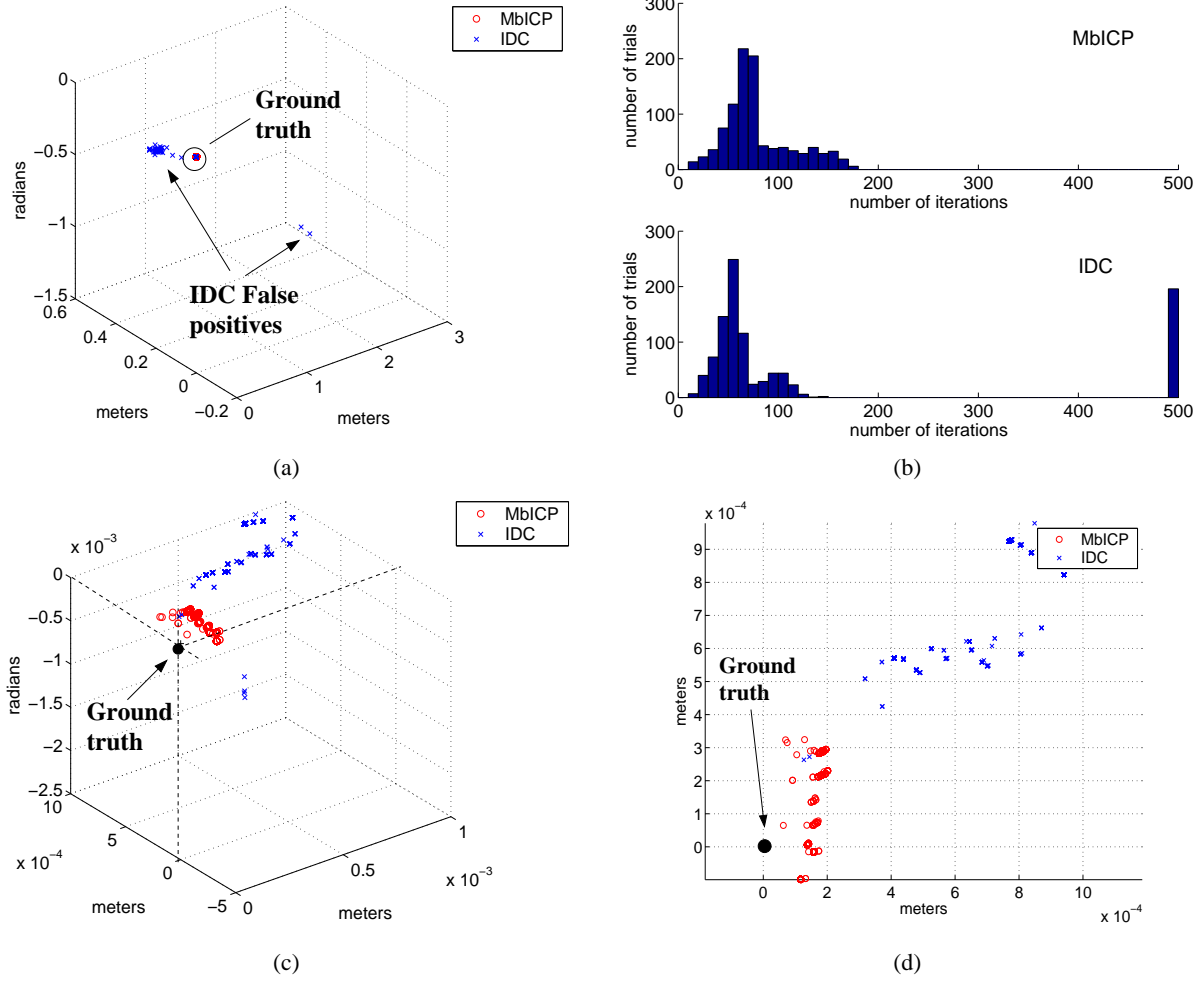

Fig. 4. (a) Estimations of both algorithms. (b) Convergence rate. (c) Zoom on the estimations around the ground truth. (d) Figure (c) projected in the XY plane.

other words, all the results of the MbICP were *True Positive* (see Table below). On the other hand, in 19.6% of the trials the IDC did not converge leading to negatives (Figure 4b). In some of them 18.6% the algorithm was close to the solution (*False Negatives*). Another measure of robustness is that some of the IDC positives were *False Positives*. They corresponded to situations where the IDC converged but towards a local minimum that did not correspond to the real solution (Figure 4a).

TABLE I
MbICP vs IDC (%)

	Positive	False Positive	Negative	False Negative
MbICP	100	0	0	0
IDC	75.2	5.2	1	18.6

The conclusion is that the MbICP is more robust than the IDC because: (i) all the results of the MbICP were *True Positives* while the IDC had *Negatives* (they correspond to large errors in orientation that could not be compensated). We think that relaxing the convergence criterion for the IDC would reduce the number of *False Negatives* but they would not disappear. And (ii) the IDC had 5.2% of *False*

Positives (also due to large errors in orientation) which are really bad for these methods since the estimate is wrong although the result is positive.

Figure 4c depicts a zoom on Figure 4a around the ground truth (0,0,0), and Figure 4d the projection on the XY plane. There we see how all the solutions of the MbICP concentrate around the ground truth, while all the IDC solutions are farther. Next table depicts the mean and standard deviation of the error in both coordinates (we only use the *True positives*):

TABLE II
MbICP vs IDC ERROR

	x error		y error		th error	
	μ	σ	μ	σ	μ	σ
MbICP (10^{-3})	0.15	0.02	0.09	0.1	0.0	0.0
IDC (10^{-3})	0.68	0.1	0.78	0.17	-0.001	0.01

In all coordinates, the medium and covariance of the errors are lower in MbICP than in the IDC. In other words, the MbICP is more accurate than the ICP.

Figure 4b depicts the number of iterations of the trials where we see how the converge rate is similar for both methods (without taking into account all the times that

Fig. 5. This Figure depicts the odometry data of a trial of 70 meters.

the IDC did not converge). We want to remark this test was carried out in extreme conditions for both methods. In real scenarios the error noise should be lower (as is the next experiment). However, the experiment illustrates the advantages in robustness and precision of the MbICP.

The second experiment corresponds to a run in our University with the wheelchair vehicle. The robot travelled 70 meters getting out of an office, travelling around a corridor and coming back to the office. The experiment is difficult because the floor was very polished and the vehicle slipped constantly with a poor effect on the odometry (Figure 5). In addition, the scenario was full of chairs, tables, baskets which are non structured, and the corridor is quite long and thus there was not many frontal structure to correct the location in this direction.

Figure 6 depicts the result with each method. We see how the visual result of the MbICP is better than the ICP since it is able to align the corridor and the office when it comes back. The rotational accumulated error is lower for the MbICP than for the IDC. Moreover, note how the error in translation is also quite small. These experiments show how the behavior of the algorithm in a complete experiment is globally better in the MbICP than in the IDC, since the MbICP is more robust and accurate than the IDC.

V. CONCLUSIONS

This paper presents a metric-based matching algorithm to estimate the robot planar displacement by matching dense two-dimensional range scans. The contribution is a geometric distance that takes into account the translation and orientation of the sensor at the same time.

We have implemented and tested the technique in a real vehicle and compared with the widely used Iterative Dual Correspondence scan matching algorithm. The results demonstrate that we improve previous methods in robustness and precision with a similar convergence rate. This is because we compensate at the same time the three variables of the minimization (two of translation and one of rotation).

h

Fig. 6. (Top) Visual map obtained with the MbICP. (Bottom) Visual map of the IDC.

Another important consequence is that our method is able to deal with large odometry errors especially in rotation (up to 45°), which is the difficulty of most of the existing approaches.

Finally we address in the next Section how this technique could be extended to be used in other contexts.

VI. DISCUSSION AND FUTURE WORK

In this Section we briefly describe some extensions and applications of this metric based scan matching technique. The first issue to address is how to extend the metric to deal with more complex systems (with crossrelations in the coordinates). This could be done by extending the norm to be:

$$||q||^2 = q^T \cdot A \cdot q \quad (11)$$

where $A = \{a_{i,j}, i, j = 1 \dots 3\}$ is a symmetric and semipositive matrix. The expression of the distance is then:

$$d^{ap} = |\delta^T \cdot Q \cdot \delta|^{\frac{1}{2}} \quad (12)$$

where $\delta = (\delta_x \ \delta_y)^T$ and:

$$Q = \begin{pmatrix} a_{11} - \frac{k_2^2}{2k_1} & a_{12} - \frac{k_2 k_3}{4k_1} \\ a_{12} - \frac{k_2 k_3}{4k_1} & a_{22} - \frac{k_3^2}{2k_1} \end{pmatrix} \quad (13)$$

$$k_1 = a_{11}p_y^2 + a_{22}p_x^2 - 2a_{12}p_x p_y - 2a_{23}p_x + 2a_{33}p_y + a_{33}$$

$$k_2 = 2(a_{11}p_y - a_{12}p_x + a_{33})$$

$$k_3 = 2(a_{12}p_y - a_{22}p_x + a_{23})$$

This expression of the distance is the generalization of the distance presented in this paper. This would allow to address the same problem but describing more complex systems.

Another important matter is the extension of the distance formulation to three dimensions. Up to now we have demonstrated that the distance is also a distance in \mathbf{R}^3 and the expression given two points p_1 and p_2 is:

$$d^{ap} = \|p_2 - p_1\|^2 - \frac{\|p_1 \otimes p_2\|^2}{\|p_1\|^2 + L^2} \quad (14)$$

This result allows to address scan matching problems in 3D workspaces and to use it in other communities that use the ICP algorithm to address sensor motion estimation, location and map building, object recognition, pattern analysis, image registration, and scene understanding among others. Up to our knowledge the idea of a unified framework to take into account translation and rotation in the ICP has not been explored in these communities yet [20].

Finally, we are exploring how this distance relates with an statistical distance called the Mahalanobis distance. More precisely, by associating the matrix A with the information matrix of vector q , and transforming it to the point location using the Jacobian of q , we obtain a matrix C defining the uncertainty of the point location. The Mahalanobis distance using C is equal to the expression of our approximate distance. However, we remark that this is true for the approximate expression of the distance (obtained linearizing). In any case, we stress that, to our knowledge, the scan- matching problem has not been addressed with the Mahalanobis distance yet. The results of this paper suggest promising research opportunities in this direction.
